River-Aquifer Interactions, Geologic Heterogeneity, and Low Flow Management
by Jan H. Fleckenstein, Richard G. Niswonger, Graham E. Fogg

Abstract

Low river flows are commonly controlled by river-aquifer exchange, the magnitude of which is governed by hydraulic properties of both aquifer and aquitard materials beneath the river. Low flows are often important ecologically. Numerical simulations were used to assess how textural heterogeneity of an alluvial system influences river seepage and low flows. The Cosumnes River in California was used as a test case. Declining fall flows in the Cosumnes River have threatened Chinook salmon runs. A groundwater-surface-water model for the lower river basin was developed, which incorporates detailed geostatistical simulations of aquifer heterogeneity. Six different realizations of heterogeneity and a homogenous model were run for a three year period. Net annual seepage from the river was found to be similar among the models. However, spatial distribution of seepage along the channel, water table configuration, and the level of local connection and disconnection between the river and aquifer showed strong variations among the different heterogeneous models. Most importantly, the heterogeneous models suggest that river seepage losses can be reduced by local reconnections, even when the regional water table remains well below the streambed. The percentage of river channel responsible for 50% of total river seepage ranged from 10 to 26% in the heterogeneous models as opposed to 23% in the homogeneous model. Differences in seepage between the models resulted in up to 13 days difference in the number of days the river was open for salmon migration during the critical fall months in one given year.

Introduction

Alluvial sediments commonly display a high degree of heterogeneity with values of hydraulic conductivity (K) spanning several orders of magnitude (Miall 1996). Interaction between an alluvial aquifer system and river will be influenced by the spatial arrangement of hydroligfacies at the interface between the river and the underlying aquifer (Woessner 2000). Consequently subsurface heterogeneity may have a profound influence on how a river responds to changes in groundwater levels. Traditionally, modeling studies that include river-aquifer interactions have been focused on questions of regional scale water management and conjunctive use (Onta 1991; Reichard 1995; Wang et al. 1995). In this context interaction between the aquifer and rivers is motivated mainly by interest in the regional water balance. Riverbed conductivities are determined by calibration and aquifers are often represented as laterally extensive layers with relatively uniform parameters.

Whereas this approach is usually sufficient for regional scale water management questions, it is inappropriate when the ecological dynamics of river-aquifer systems are investigated (Woessner 2000). Although various case studies address the impacts of river-aquifer interactions on stream flows (Kondolf 1987; Pucci and Pope 1995; Tabidian et al. 1995; Perkins and Sophocleous 1999; Ramireddigary 2000), aquifer heterogeneity is rarely addressed. Exceptions are studies by Wroblicky et al. (1998), Hathaway et al. (2002) and Kollet et al. (2002 and 2003). Wroblicky et al. (1998) identified aquifer heterogeneity as one of three major controls on river-aquifer exchange in two first order streams in New Mexico. Similarly, in a field study of Prairie Creek in Nebraska, Kollet et al. (2002) demonstrated the importance of aquifer heterogeneity on river-aquifer interactions. Hathaway et al. (2002) stress the importance of lithologic characterization of the upper 15 m (~50 ft) of the alluvial system to account for changes in soil moisture and the development of perched saturated zones that influence river-aquifer exchange on the San Joaquin River in California. Various modeling studies of hypothetical river-aquifer systems have also looked at effects of aquifer heterogeneity and varying anisotropy on river-aquifer exchange in hydraulically connected and disconnected systems (Peterson and Wilson 1988; Sophocleous et al. 1995; Bruen and Osman 2004).
In recent years a growing number of studies have focused on small scale river-aquifer interactions and the role of the hyporheic zone in stream ecosystems (Wroblicky et al. 1998; Woessner 2000; Hathaway et al. 2002; Malcom and Soulsby 2002; Storey et al. 2003; Gooseff et al. 2003; Kasahara and Wondzell 2003; Rodgers et al. 2004). These studies adopt a local-scale perspective and address spatial and temporal variability of river-aquifer exchange, but they have primarily focused on small streams and low order drainages in mountainous terrain.

Despite this growing interest in river-aquifer interactions, investigations of the effects of subsurface heterogeneity on river-aquifer exchange on larger scales are lacking. When the scope expands to regional scales on the order of $10^1$ km and above, the heterogeneities of concern typically include substantial volumes of both aquifer and aquitard materials (e.g. sands/gravels and silts/clays) as well as facies of intermediate K (e.g., silty sands). In an alluvial or fluvial depositional system, flow and transport tends to be dominated by the volume fractions, geometries and connectivities of such hydrofacies (Fogg 1986; Ritzi et al. 1995; LaBolle and Fogg 2001; Weissmann et al. 2002). Powerful geostatistical techniques have become available for modeling the hydrofacies in three dimensions and have been used in studies of groundwater flow and transport (Scheibe and Yabusaki 1998; LaBolle and Fogg 2001).

In this work we use geostatistical indicator simulations to incorporate structural heterogeneity of hydrofacies into a numerical model that simulates river flow, vertical unsaturated flow and three-dimensional groundwater flow. The model was constructed for the alluvial lower basin of the Cosumnes River in California, which provides a test case for the investigations.

Objectives

The main objective of this paper is to examine the effects of hydrofacies-scale subsurface heterogeneity on river-aquifer interactions and river flow. We consider this problem in the context of low flows and their effects on the riparian ecosystem and salmon migration in alluvial rivers. Based on field evidence from the Cosumnes River in California we hypothesize that the spatial arrangement of hydrofacies between the river and the aquifer may have significant impacts on river-aquifer exchange and river flows. To test the hypothesis we simulate river-aquifer interactions for six geostatistical subsurface models, which were created based on geologic data from the lower Cosumnes River basin.

Background

The Study Area

The Cosumnes is the last major undammed river in California. Its watershed is located on the western side of the Sierra Nevada in Amador, El Dorado, and Sacramento Counties, California (Figure 1). The basin covers an area of approximately 3,400 km² and ranges in elevation from 2,400 m above mean sea level (amsl) at the headwaters to near sea level at its outlet in the Sacramento/San Joaquin Delta. In the upper mountainous basin, the Cosumnes River is comprised of 3 forks, which join near Michigan Bar (MHB). At MHB the river enters its lower basin which is characterized by the alluvial fan topography of the Central Valley of California. Deer Creek is the main tributary to the Cosumnes and enters the channel at the McConnell (MCC) gage (Figure 1). In the lower basin the river flows through groundwater bearing sedimentary deposits of Tertiary and Quaternary age. The Climate is of the Mediterranean type with strong seasonality in rainfall. About 75% of annual precipitation occurs between November and March (PWA 1997).

Historically the river supported large fall runs of Chinook salmon (TNC, 1997). Decreasing fish counts in recent years have been linked to declining fall flows. Severe overdraft of groundwater in the alluvial lower basin since the 1940s (Montgomery Watson, 1993b) has lowered the regional water table below the elevation of most of the river channel, largely eliminating base flows. Simulations of regional groundwater flow have demonstrated that large amounts of water would be needed to reconnect the regional aquifer with the river (Fleckenstein et al. 2001; 2004). However, field observations along the river indicate the formation of local saturated zones in the shallow subsurface below the river channel during the wet season. Local reconnection between the river and groundwater appears to be caused by the structure of subsurface heterogeneity and can decrease seepage losses from the river or even create gaining conditions. Areas of local connection could provide opportunities for the reestablishment of base flows and restoration of fall flows without having to restore regional groundwater levels. Management of low flows has become an important issue on the lower Cosumnes River as well as in other arid and semiarid basins (Ponce and Lindquist 1990; Shrier et al. 2002). Hence a better understanding of the effects of aquifer heterogeneity on low flows in alluvial rivers could help the development of future flow restoration and management strategies on the Cosumnes and elsewhere.

Flow conditions and salmon runs

Historical flows in the Cosumnes River range from no flow in late summer and early fall during dry to moderate years to a peak flow of 2,650 m³/s (93,584 cfs) at MHB during a 1997 flood. Base flows along the lower river have practically been eliminated along extended reaches of the river as a result of lowered water tables. Unsaturated zones have formed between the river and the regional aquifer in those reaches. The annual fall run of Chinook salmon on the Cosumnes River occurs from early October through late December, with a peak in November. Historic runs range from 0 to 5,000 fish, while the basin has been estimated to have a capacity to handle runs of up to 17,000 fish under suitable flow conditions (USFWS 1995; TNC 1997). During 1997-2001 Chinook salmon runs of 100 to 580 fish have been estimated based on carcass counts (Keith Whitener, The Nature Conservancy, oral communication, 2002). Exacerbated dry and low flow conditions in the river, which extend further and further into the fall salmon migration period are the main obstacle for successful salmon spawning.

Methods

The study combines geostatistical simulation of hydrofacies with transient numerical modeling of groundwater flow and river-aquifer interactions. An upscaling method involving simple averaging and global readjustment of K values based on numerical experiments (Fleckenstein 2004) was used to upscale hydraulic parameters from the highly resolved geostatistical models to a coarser flow model. The analysis was conducted on an intermediate scale so that model cells were appropriately sized to consider the scale of heterogeneity and the model domain large enough to include the entire alluvial river corridor and large parts of the regional aquifer system. Conditional sequential indicator simulations based on Markov Chain models of transition probabilities were used to model aquifer heterogeneity to a depth of 60 m below the surface. Deeper aquifers were described with data from an existing finite element (FE) regional groundwater model (Montgomery Watson 1993b). Different realizations of aquifer heterogeneity

Fleckenstein et al. in press, GROUND WATER, Special issue from MODFLOW and more conference, 2003

3
were created to elucidate the impacts of different hydrofacies arrangements on river-aquifer exchange processes not to attempt a full stochastic treatment of uncertainty with a large number of realizations (e.g. Monte Carlo analysis). A river scale groundwater flow model, embedded in a larger regional flow field, was developed to quantify river-aquifer exchange, river recharge and fall river flows for different hydrofacies arrangements. Boundary conditions for the river-scale model were calculated with the regional groundwater flow model as described below (Montgomery Watson 1993b).

Structural alluvial fan heterogeneity and Geostatistical Simulation

The difficulty of characterizing subsurface heterogeneity is a major obstacle to building realistic groundwater flow and transport models. A significant amount of research has been directed towards methods to characterize subsurface heterogeneity. Koltermann and Gorelick (1996) and de Marsily et al (1998) give extensive reviews of different approaches. Conditional indicator simulation has been proven to be a powerful geostatistical tool to create realistic images of alluvial subsurface heterogeneity (Carle et al. 1998; Weissmann et al. 1999; Weissmann and Fogg 1999; Ritzi et al. 1995 and 2000). Carle and Fogg (1996; 1997) and Carle et al. (1998) have demonstrated that 3D Markov Chain models of transition probabilities between hydrofacies (indicators) can be used as an alternative model of spatial correlation to the traditional variogram or covariance models.

In contrast to approaches based on variogram or covariance models, the transition probability based model can be used to translate geologic conceptual models into probabilistically consistent, 3-D hydro-facies models based on both hard and soft geologic and geophysical data. Transition probabilities, estimated from observed hydrofacies arrangements. Boundary conditions for the river-scale model were calculated with the regional groundwater flow model as described below (Montgomery Watson 1993b).

Global proportions of facies can be calculated from the driller’s log data under the assumption of spatial stationarity. Mean facies length and juxtapositional tendencies can be inferred from knowledge of the depositional environment, geologic maps or from soil surveys (Weissmann et al. 1999; Weissmann and Fogg 1999). From the transition rate matrices a continuous lag Markov Chain model is developed, which is used with cokriging in a sequential indicator simulation (SIS) to generate images of subsurface facies distributions (Deutsch and Journel 1998; Carle and Fogg 1997). Computation of transition probabilities and transition rate matrices from the driller’s log data, derivation of the Markov Chain models and SIS are carried out with the software TPROGS (Carle 1999).

Hydrofacies of the Cosumnes River Fan

Sediments in the lower Cosumnes River basin are comprised of alluvial fan sediments that were deposited by the Cosumnes and American Rivers. The main groundwater bearing units are the Quaternary Riverbank, and the Tertiary Laguna and Mehrten Formations. Lithologically the Pleistocene Riverbank and the underlying Pleistocene/Pliocene Laguna Formation are practically not differentiable (DWR 1974). They consist of a brown to tan assemblage of granitic sand, silt and clay with channel gravel bodies mainly comprised of metamorphic rock fragments and will in the following be referred to as Laguna-Riverbank complex. The underlying Miocene Mehrten Formation also consists of clays, silts, sands and gravels but is andesitic in character and of darker gray to blackish color. The Laguna-Riverbank complex is up to 100 m thick in the study area. The Mehrten Formation ranges in thickness from tens of meters in the east to several hundred meters in the west. About 350 driller’s logs from the study area, almost exclusively from the Laguna-Riverbank complex, were obtained from the California Department of Water Resources (DWR) and analyzed. Based on the quality and consistency of the driller’s descriptions, a subset of 230 logs (Figure 1) was chosen (mainly drilled with a cable tool). Sediment descriptions within that subset were grouped into four distinct hydrofacies (Table 1), gravel and coarse sand, sand, muddy sand and mud (silt and/or clay undifferentiated). Those hydrofacies were not further differentiated between the lithologically similar Riverbank and Laguna formations, both of which were deposited in the same type of alluvial environment. A similar classification was made by Weissmann and Fogg (1999) in a study of the King’s River alluvial fan.

The gravel-coarse sand and sand hydofacies represent channel deposits. Weissmann and Fogg (1999) called these units the channel facies assemblage. The muddy sands hydofacies are comprised of silty and clayey sands and sandy silts and clays and characterize the transitional zone between channel and floodplain deposits. They are typically found in the proximity of the channel (Weissmann and Fogg 1999). The mud hydofacies combine all floodplain deposits, typically assemblages of silts and clays mixed with some fine sands.

Development of Model of Spatial Correlation

Data from the selected 230 driller’s logs (16,700 m of log description) were discretized into 0.5 m increments. With this vertical resolution the smallest hydofacies thicknesses of around 2.8 m (Table 2) could be represented by at least 4 to 5 grid cells in the geostatistical model. That ensures realistic shapes of hydofacies bodies in the indicator simulation. Vertical transition probabilities and Markov chain models were determined from the log data using TPROGS. Figure 2 shows the transition probability matrix and fitted Markov Chain models in the vertical direction. The fitted Markov chain models deviate from the maximum entropy model (Carle and Fogg 1997; Carle et al. 1998), which disregards directional asymmetries, indicating directional trends in hydofacies arrangements. Slight fining upward sequences can be seen in the gravel and coarse sand to muddy sand transition (Figure 2). Lateral spacing of the driller’s log data was too sparse to yield meaningful transition probability matrices for the dip and strike directions. Therefore embedded transition probability matrices were developed from estimates of mean hydofacies length, volumetric hydofacies proportions and knowledge of lateral juxtapositioning of hydofacies (see Weissmann and Fogg 1999 and Weissmann et al. 1999 for examples of this procedure).

First, estimates of mean length of the channel hydofacies in the dip and strike directions were made from regional maps of channel deposits in the shallow subsurface (from DWR 1974). Obtained values were compared with values from other studies in similar alluvial fan settings in California (Kings River, American River) and found to be in reasonable agreement (Weissmann and Fogg 1999; Elliot 2002). Table 2 shows the embedded transition probability matrices for the hydofacies of the Laguna-Riverbank complex in the dip-, strike- and vertical-directions. A final 3D Markov chain model was developed from the developed embedded transition probability matrices in the horizontal directions and the calculated transition rate matrices in the vertical direction.

Sequential Indicator Simulations (SIS)

The final Markov Chain model was used as input for the sequential indicator simulation routine in TPROGS. The model domain covers a 10 by 40 km area to a depth of 60 m (Figure 1). Cell dimensions in the simulation grid were 100m, 200m and 0.5m in the dip-, strike- and vertical-directions, respectively, yielding a final simulation grid of more than 4 million cells. Within the model domain the alluvial sediments dip at angles between 0.03 and 1.13 degrees, with steeper angles in the deeper Merhten Formation. To estimate dip angles of the facies within the 3D model domain elevations of sequence boundaries between the Mehrten, Laguna and Riverbank formations from geologic crosssections (DWR 1974) were kriged. Dip angles were then calculated along sequence boundaries. Finally dip-angles in the vertical were linearly interpolated between sequence boundaries, yielding a 3D array of dip-angles for the model domain. Six different realizations of the model (R1 to R6) were generated (Figure 3). When the Monte-Carlo method is used to account for uncertainty, one would typically create hundreds of realizations. In this case, however, the purpose of the stochastic realizations was to investigate processes related to heterogeneity, and not to estimate the full range of possible outcomes or the ensemble statistics of the flow model results. The six realizations provide insights into the degree of variability that one can anticipate among realizations while still keeping the numerical experiment computationally tractable.

River-scale groundwater-surface water modeling

The Numerical Code

The finite difference numerical groundwater flow code MODFLOW-2000 (McDonald and Harbaugh 1988, Harbaugh at al. 2000) was used for the groundwater flow simulations. River flows are simulated with a new version of the MODFLOW stream package (Prudic et al. 2004) that includes the ability to simulate 1D unsaturated flow using a kinematic wave approximation to Richard’s equation (Niswonger and Prudic 2004). This package was chosen because extended reaches of the lower Cosumnes River are underlain by variably saturated zones that have developed between the river and the aquifer. The combination of a Lagrangian solution to vertical unsaturated flow with the Eulerian finite difference solution in MODFLOW, allows the unsaturated flow simulation to be independent of the grid discretization and time stepping in the groundwater flow solution. This relaxes the requirement for very small time steps and fine grid discretization, that are required when using numerical solutions of Richards equation. This was an important criterion in the choice of a numerical code.

The kinematic wave approximation to Richard’s equation in 1D, assumes vertical, gravity driven flow and capillarity is neglected (Smith 1983). Niswonger and Prudic (2004) showed that this is an acceptable assumption for typical alluvial sediments. The saturation-conductivity relationship is represented by the Brooks and Corey equation. Flow routing in the stream package is based on the continuity equation and the assumption of piecewise steady and uniform flow. Flow depth in the river can be calculated from 8-point cross-sections specified for each river segment (Prudic et al. 2004). The unsaturated zone below the river is discretized into 10 panels across the width of the channel, within which water seeping from the channel is routed to the water table as kinematic waves (Niswonger and Prudic 2004). Seepage is calculated from the product of the head gradient times a streambed conductance. In the case of a fully saturated hydraulic connection between the river and aquifer, the head gradient is calculated as the head difference between the river and underlying aquifer divided by the streambed thickness. A uniform streambed thickness of 1m was used in the model. For the disconnected case, the head difference is assessed between the river stage and the head at the bottom of the streambed, which can be negative (suction pressure). An upper limit is imposed on seepage from the river if the seepage flux exceeds the capacity of the unsaturated zone to accommodate and convey the calculated seepage flux. Thus river seepage becomes a function not only of streambed K, but also of vertical conductivity of the aquifer or vadose zone.

Upscaling of Aquifer Hydraulic Parameters

Values of hydraulic conductivity, specific yield, and storage coefficient were assigned to each of the four hydrofacies within the geostatistical model. Initial parameters were estimated from well-test results, literature values (Domenico and Schwartz 1998; Smith and Wheatcraft 1993) and other studies in similar alluvial settings (Weissmann and Fogg 1999; Elliot 2002) (Table 3). The 4 million cells in the geostatistical model grid would have created an intractable flow model grid. The total number of grid cells in the flow model was reduced by upscaling hydraulic parameters in the vertical columns from 0.5 m in the geostatistical model to 5-40 m in the final flow model. The lateral discretization is preserved with model grid dimensions of 200 m and 100 m in the dip and strike directions, respectively. Effective horizontal K within the vertical model columns was calculated from the weighted arithmetic mean of the hydrofacies conductivities within the column. Effective vertical K was obtained from the weighted harmonic mean. A similar upscaling procedure is implemented in the HUF-package for MODFLOW (Anderman and Hill 2000).

Systematic adjustments were made to the upcaled values to account for the fact that this procedure results in drift of the upcaled K values away from the true, effective K values. Those adjustments were based on numerical experiments in which we assessed the effects of upscaling on groundwater flow through the model by running steady state flow simulations for a 10000 x 10000 x 120 m block of the model with constant head boundaries on two, opposing sides and no-flow boundaries on all other sides for various levels of upscaling and five realizations of the geostatistical model. A consistent logarithmic increase in flow through the blocks with increasing upscaling was found for all five realizations. The increase in K was caused by increased conductances between the larger upscaled

Fleckenstein et al. in press, GROUND WATER, Special issue from MODFLOW and more conference, 2003
grid blocks (Fleckenstein 2004). Based on that relationship the upscaled K field was corrected for scaling effects by multiplying model grid block K values by a correction factor (< 1). Effective specific yields and storage coefficients for the upscaled model were estimated from the weighted arithmetic mean of the hydrofacies values. A more detailed description of this procedure is given in Fleckenstein (2004).

**Model Design and Boundary Conditions**

The flow model covers a 10 by 40 km corridor around the lower Cosumnes River (Figure 1) and is comprised of nine layers. The five uppermost layers represent alluvial deposits of the Riverbank and Laguna Formations. These layers range in thickness from 40 m (top layer) to 5 m (second to fifth layers). They are parameterized based on the upscaled hydrofacies parameters from the geostatistical simulations. Northeast of the geostatistical model domain (Figure 1), deeper Tertiary formations that crop out at the surface were not included in the geostatistical model so as not to violate the stationarity assumption. In this area the flow model domain was extended to the boundary between the Tertiary alluvium and the bedrock of the Sierra Nevada foothills (Figures 4 and 5).

Parameters for the extension of the flow model were obtained from a regional FE groundwater model (Montgomery Watson 1993b). The top layer was modeled as unconfined and was kept thick enough to capture the large variations in water table elevations encountered in the model domain in order to avoid drying and wetting of cells in MODFLOW. The deeper layers (layers 6-9) represent the deeper alluvial aquifer down to the bottom of the alluvial basin. They are mainly comprised of deposits of the Tertiary Mehrten Formation and range in thickness from 40 to more than 400 m. Hydraulic parameters in these layers were assigned from the regional FE groundwater model. Specified head boundary conditions were applied along the northeast and southwest boundaries of the model based on long term average water levels from nearby wells. At the southwest boundary the model borders the Sacramento San Joaquin Delta, which is tidally influenced, and heads in the first layer are fixed at mean sea level. Vertical hydraulic gradients along these model boundaries were established based on observed vertical gradients and gradients simulated in the regional groundwater model. Specified flux boundary conditions were assigned to the northwest and southeast boundaries of the model in the uppermost five heterogeneous layers of the model. The regional FE model (Montgomery Watson 1993b) was used to estimate these boundary fluxes. Simulated fluxes in the regional model showed relatively small seasonal fluctuations. Therefore average annual fluxes were used. Boundary conditions for layers 6 to 9 were specified as general head boundaries. General heads
were calculated from the 15-year average head values 1,000 m away from the model boundary as simulated with the regional model. Over this period, heads in the deeper aquifer were reasonably stable. Conductances were calculated from the arithmetic mean of the K values in the regional model at the boundary nodes and the general head locations.

The base of the model is treated as a no-flow boundary, consistent with the regional stratigraphy and the regional model of Montgomery Watson (1993a). Average annual recharge was estimated with the regional model, which calculates spatially variable percolation to the water table based on precipitation, irrigation applications, and soil types. Estimated average annual recharge varied from 25 to 275 mm in the model area. Monthly groundwater pumping was assigned based on pumping in the regional model (Montgomery Watson 1993b). River inflows into the model domain were specified as mean daily flows from the gage at MHB for the Cosumnes River and estimated from a stage discharge relationship and a stage record for Deer Creek. Channel geometries were characterized using 109 cross-sections from recent surveys (Guay et al. 1998; Constantine 2003). Riverbed K values for each of the 109 river segments were calculated from the arithmetic mean of the vertical K values of the river cells contained within each segment. It was assumed that the geologic strata are a good approximation of the regional riverbed K values because the Cosumnes River has downcut into the native sediments. Length of the river reaches ranged from 70 to 200m (average length = 170m) with 1 to 10 reaches per segment. Statistics on riverbed K for the different models are listed in Table 5.

Calibration

Goal of the calibration was to find one set of hydrofacies parameters (K, specific yield, specific storage) that would result in a reasonable fit between simulated and observed heads and annual river seepage for all realizations of heterogeneity. This approach allows the importance of subsurface heterogeneities to river seepage to be evaluated while maintaining tractable model execution times. R-values larger than 0.9 for heads and simulated annual river seepage volumes within the range of estimated values (DWR 1974) were considered a reasonable fit.

First, transient model runs for the six realizations of heterogeneity were performed with initial guesses of the hydrofacies parameters. Simulated heads and total river seepage were compared to observed values for all runs. Then hydraulic parameters of the individual hydrofacies (K, specific yield and specific storage) were adjusted by trial and error to improve model fit. Parameter values were upscaled again using the upscaling procedure outlined above.

Finally the model was run for the three water years 2000-2002 with daily stress periods and 3 hour time steps. Daily stress periods were necessary to accommodate daily river flows. Groundwater pumping changed on a monthly time scale. The main calibration targets were: observed groundwater levels in 16 monitoring wells throughout the model domain (nine of which are in the vicinity of the river channel); a stage record on the Cosumnes River at McConnell (MCC); and net annual river seepage as estimated from an earlier study (DWR 1974).

This process was repeated until a reasonable match between simulated and observed values was achieved (Table 6, Figures 6 to 8). The final hydraulic parameters of the final model are shown in Table 4. The RMSE for simulated hydraulic heads in the final models ranged from 1.94 m to 4.24 m and the correlation coefficient (Hill, 1998) was between 0.94 and 0.98 (Table 6).

Model Runs

After calibration, the model was run for the six different realizations of geologic heterogeneity (R1 to R6) using the calibrated hydrofacies parameters. For comparison, a homogeneous model was run, which used the arithmetic and harmonic means of the calibrated hydrofacies conductivities, weighted by their volumetric proportions, as uniform vertical and horizontal conductivities.

Initial estimates of riverbed conductivities in the homogenous model were calculated from the geometric mean of the river reach conductivities in the calibrated heterogeneous model (R1). Then those values were separately calibrated. All models were run for the same 3-year period (water years 2000-2002) that was used in the calibration process.

Results and Discussion

Geologic Heterogeneity and Spatial Variability of Seepage

Average annual seepage amounts from the river system for the different model runs are shown in Figure 9. Total seepage from the river between MHB and MCC ranged between 72 and 100 million m³ per year. All values were within half a standard deviation (1/2σ = 27 million m³) of the mean (µ = 89 million m³) of annual river seepage estimates between those two gages made by the Department of Water Resources using river flow records (DWR 1974).

All models yielded similar calibration statistics, net annual seepage volumes and overall water budgets and are consistent with what is known about the regional hydrology. Local simulated seepage rates along the channel, however, were found to be highly variable in space and time both within and among the heterogeneous models. Temporal variability of seepage was driven by the river inflow hydrograph and the resulting availability of water in the channel in combination with riverbed geometry and resulting river stage. Spatial variability was mainly governed by the distribution of hydrofacies and the corresponding riverbed conductivities along the channel. Figure 10 shows simulated seepage rates along the channel for a moderate flow event (24 m³/s on April 14, 2000) and a high flow event (202 m³/s on February 28, 2000) for five heterogeneous and the homogenous models. Seepage in the homogeneous model was relatively uniform.

Smaller fluctuations occurred mainly due to changes in cross-section geometry. In contrast, seepage rates in the heterogeneous models showed large variability along the channel and among realizations despite similar means and variances of riverbed conductivities (Table 5).

All realizations except R1 showed areas of high seepage between river kilometers 17 and 27. R3 also showed high seepage around river kilometer 10, whereas R5 displayed higher seepage at kilometer 38. These results show that most river recharge to the regional aquifer can occur in only a few localized areas where the riverbed and underlying aquifer are most conductive. About 23% of the river channel contributed 50% of total seepage in the homogeneous model during the moderate and high flow events. In contrast, the percentage of channel that was responsible for the same 50% in seepage in the heterogeneous models ranged from only 10 to 26% (Table 7).

Figure 9. Simulated net annual seepage volumes for the different models compared to an estimate from a field study, (net seepage is the sum of “positive” flux from the river to the aquifer and “negative” flux from the aquifer to the river).

Whereas the percentages of channel length contributing half of all seepage were similar for the moderate and high flow events, total seepage volumes did vary.
Spatially focused seepage in the heterogeneous models resulted in larger total seepage volumes during moderate flow. During high flows in contrast, focused seepage eventually raised the water table to the river bed thereby reducing seepage. Therefore the homogeneous model showed the highest total seepage during high flow (202 m$^3$/s) but only ranked fourth during moderate flow (24 m$^3$/s).

Geologic Heterogeneity and Groundwater Levels

The configuration of the water table below the river channel showed significant variations between different models. Figure 11 depicts the water table below the river channel in the fall and spring of year two of the 3-year simulation period. All simulations show the same overall features where the water table connects with the riverbed at the furthest upstream and downstream ends of the model domain and substantial separation between the water table and the riverbed in between.

The configuration of the water table below the river channel shows large local variations between different realizations of the heterogeneous model. These variations are most pronounced during and immediately after the wet season, when river flows are high (Figure 11). During the fall, when most of the river channel is dry, variations are small and mainly due to variations in the water table configuration from the preceding wet season in the model. During the wet season variable seepage causes local reconnections between the aquifer and the river channel upstream of MCC in realizations R2, R3 and R4, whereas R1, R5 and R6 and the homogeneous model remain disconnected.

These reconnections could explain seasonally observed gaining conditions in some reaches of the river during seepage measurements with seepage meters. If reconnections only occur locally they likely would not be detected in a sparse monitoring network as used in this study. For most monitoring wells in the vicinity of the river that were available in this study, well depth and location of screens were not known, although most of the wells appear to be screened in confined zones. Observed groundwater levels could therefore represent lower heads in the deeper aquifer rather than water table levels immediately below the river channel.

Figure 10. Simulated seepage rates along the river channel - February 28, 2000 (A) and April 14, 2000 (B), (results from R4 were very similar to R3 and were omitted for readability, positive seepage is from the river to the aquifer, rates are in m$^3$/s per river cell – average length of channel in river cell = 180 m).

Figure 11. Simulated water table below the river channel - September 29, 2000. (A) and April 14, 2001 (B).

Water table contours in plan view show differences among the different models mainly around the river (Figure 12). In the homogenous model, river seepage can
travel toward the boundaries faster. Groundwater levels at the boundaries of the homogenous model are therefore substantially higher than in the heterogeneous models and than observed in the field.

**Figure 12.** Groundwater contours in layer 1, April 2001 for four heterogeneous and the homogeneous models.

Implications for Low Flows

Simulated annual seepage amounts were small relative to total annual river flows. They only constituted between 8.1 and 9.6% of total annual flow. During low flow periods, however, seepage capacity can locally exceed river inflows. Consequently, spatial distribution and timing of seepage can have significant impacts on minimum river flows during those periods. A minimum flow of about 0.56 m$^3$/s (20 cfs), which roughly corresponds to a flow depths of 0.2 m on the Cosumnes, was considered sufficient to allow fish passage (Keith Whitener, oral communication, 2002). The number of days with flows above that threshold (evaluated at eight locations along the channel) during the critical fall migration period for Chinook Salmon (October to November) varied significantly between the different models of heterogeneity. Numbers ranged from 0 to 3 days for year one, 1 to 6 for year two and 23 to 36 for year three (Figure 13).

![Figure 13. Number of days in Oct., Nov. and Dec. with flow >0.56m$^3$/s (20cfs) for the three years of the simulation. Year was the year with the earliest fall precipitation.](image)

**Figure 13.** Number of days in Oct., Nov. and Dec. with flow >0.56 m$^3$/s (20cfs) for the three years of the simulation. Year was the year with the earliest fall precipitation.

Discussion

The simulation results show that alluvial river-aquifer systems like in the lower Cosumnes basin are strongly influenced by river seepage, which is sensitive to aquifer heterogeneity. Different arrangements of hydrofacies cause spatial variability in seepage, which in turn has significant impacts on connectivity between the river and aquifer and the configuration of the water table in the vicinity of the river. Spatially focused seepage from the channel can result in localized groundwater mounding or the formation of perched water tables, which could reduce or even reverse the seepage gradient across the riverbed. Such conditions were reported by
Hathaway et al. (2002) on the San Joaquin River in California. Evidence for similar conditions was found on the Cosumnes River during field measurements of groundwater levels and soil moisture (Richard Niswonger, unpublished data). Attempts to simulate those local effects of river-aquifer exchange in a river-scale model are usually hampered by the lack of field data on riverbed conductivities and near channel groundwater heads, which are seldom available at the appropriate scale. Regional groundwater monitoring networks usually do not have the necessary spatial density in the vicinity of the river to reliably calibrate local riverbed conductivities. Therefore local conditions at the interface between the river and the aquifer may not be adequately represented in a calibrated model. In intermittent or ephemeral rivers, however, they can control when and where the flow ceases in the channel with consequences for fish migration.

In this study riverbed conductivities were assigned based on the assumption that in an incising alluvial river hydraulic parameters of the riverbed can be inferred from the underlying aquifer hydrofacies. Six heterogeneous models with a single set of hydrofacies parameters and one homogeneous model were calibrated to yield similar measures of model fit (RMSE, $R^2$, and overall water balance). But they showed significant differences in local seepage and river flows. This suggests that available observation data such as groundwater heads and mean annual river seepage do not provide enough information to resolve aspects of the structural geology important for assessing river-aquifer exchange. These results highlight the importance of representing geologic heterogeneity in groundwater-surface water models at a scale that can influence channel seepage and resulting low flow conditions. The geostatistical approach can provide a means to estimate spatially varying riverbed conductivities based on aquifer heterogeneity.

**Summary and Conclusions**

Simulation results showed that intermediate scale (10$^2$ m) aquifer heterogeneity can have significant impacts on the spatial distribution of river seepage. Such variability has important implications for management of low flows in intermittent and ephemeral rivers in arid and semi-arid regions. Although net annual seepage amounts were comparable among models using different realizations of subsurface heterogeneity, and a homogeneous model, local seepage rates were highly variable among models.

Simulation results for the Cosumnes River suggest that differences in the duration of minimum fall flows for salmon migration could be as long as two weeks between different models of hydrofacies distributions. The model further indicates that, owing to the facies-scale heterogeneity in a stream-aquifer system, where the water table normally lies up to 15 m below the channel, localized zones of high seepage might create local reconnections between the river and the aquifer. This condition may only exist seasonally after larger flow events. Connected zones have the potential to reduce seepage losses, contribute to base flow, and may also provide benefits for riparian vegetation. The fact that these zones may not be captured during the calibration process if monitoring data are sparse, highlights the importance of a detailed characterization of the interface between the river and aquifer (e.g. riverbed K values). This point is also made by Wroblicky et al. (1998), who identified aquifer and riverbed heterogeneity as a major control on hyporheic exchange. At the scale relevant to water management decisions (river or basin scale), however, such detail is often difficult to achieve. Finding a sensible compromise between data availability and model complexity is an important area of future research. Future work also remains to evaluate the effects of perched aquifers, which may form above the regional aquifer due to small scale aquifer heterogeneities below the river. At this point such phenomena, which can have implications for local seepage processes, are impractical to model on larger scales. Reach scale field and modeling studies could help to elucidate these processes.

In this study the use of simple upscaling relations for hydraulic parameters and a Lagrangian approach to represent variably saturated flow between the river and aquifer allowed the development of a numerically efficient model for a large, complex river-aquifer system. The model was able to represent the major features of the alluvial river-aquifer system of the lower Cosumnes River including complex heterogeneity of the alluvial aquifer. Results demonstrate the importance of including geologic heterogeneity on the hydrofacies scale in river-aquifer models to simulate river-aquifer exchange and resulting low flows.

**Acknowledgements**

The authors would like to thank CALFED for their funding through the California Bay-Delta Authority's Ecosystem Restoration Program: Grants ERP #99-NO6 and ERP #01-NO1. Support and help from various people at The Nature Conservancy's Cosumnes River Preserve, the Center for Watershed Science and Management at UC Davis and landowners, who allowed access to field sites is also greatly appreciated. Finally we want to thank the three reviewers Mary Hill, Timothy Scheibe and Mike Gooseff, as well as Keith Halford for their constructive comments and suggestions, which helped to improve the final manuscript.
